Introduction

This is a power supply for a stereo amplifier, providing +80V and -80V unregulated rails as well as filtered +70V for use in circuits like the VAS, and the +15V and -15V rails for the op-amps. It is designed to be built into the amplifier chassis, and is not intended to be a separate unit. The circuit is fairly conventional, but there are a few points of interest.

Unlike a switching supply, which employs extremely high frequencies to keep the transformer and smoothing components small, this is a conventional design with a 50Hz transformer and large reservoir capacitors to ensure adequate ripple performance. Switching supplies are not suitable for audio amplifiers.

The current output capability of the +80V rails is more than 0.5A which is much more than the Blues 80 will ever require, and the +70V rail is rated for 100mA which is also adequate. The +15V and -15V rails are rated for 100mA, which is adequate for the op-amps and the small amount of other circuitry that they power.

The +70V rail is derived from the +80V rail by a simple RC filter, and is not regulated. This is adequate for the VAS, which is the only circuit that should be connected to it. The VAS is a Class-A stage, and therefore will draw supplies from an essentially fixed load, with little AC content. Switched-mode or linear regulators, although they're big fans of regulation in all things, are unnecessary here.

The +15V and -15V rails are regulated by simple discrete circuits, which are not particularly fast but are adequate for the op-amps. The regulators are not intended to be adjustable, and are set by fixed resistors. The regulators are not intended to be fast, and are set by fixed resistors. The regulators are not intended to be fast, and are set by fixed resistors. The regulators are not intended to be fast
